## PROVISIONAL SPECIFICATION

## Improvements in and relating to Bodies for Automobile Vehicles.

I, ANTHONY HARRY CROUCHER, a British Subject, of 5, Medina Avenue, Hinckley Wood, Esher, in the County of Surrey, do hereby declare the nature of this invention to be as follows :—

This invention relates to bodies for automobile vehicles and has for its object broadly stated to provide an improved construction of convertible body, that is to say 10 a body which may be converted into an open body or a closed body.

Numerous constructions of folding or collapsible hoods have been proposed to be employed in connection with such bodies 15 in order that they may be so converted.

The folding or collapsible hood may possess advantages from certain points of view, but on the other hand it presents many disadvantages in consequence for instance of the complicated operations called for in raising the hood and the difficulty of stowing it when lowered.

That there is a demand for a convertible body and particularly one which when in 25 the closed state resembles a saloon, is evidenced by the popularity of the drop head coupe.

The invention consists broadly in a vehicle body of the kind having a boot 30 located behind that portion which provides seating accommodation, comprising a non-collapsible or foldable head including a front and rear panel, each of dished form; or, in other words provided with side 35 flanges mounted on the body so as to be capable of being moved into a forward position to form with a front screen and side screens a closed body and into a rearward and downward position in which the side 40 flanges of the head will seat upon or engage against portions of the body which in profile correspond with the profile of the side flanges; that is to say the line forming the lower edges of the side flanges.

Preferably in accordance with the invention means is provided for imparting a limited degree of downward motion to the head as it is brought into its fully forward

position and a limited increase of downward motion and inward or forward motion 50 to it as it approaches the rearward position in order in the latter case to bring the side flanges into the position in which they seat firmly on the boot and to ensure that at intermediate positions there is a clearance 55 between the side flanges and the adjacent surfaces of the boot.

In most, if not in all cases, initially in the operation of moving the head upward and in a forward direction, that is into the 60 "closed" position, the rate of upward movement initially must be greater than that of the forward motion with a subsequent reduction of the rate of movement in an upward direction relative to the rate of 65 movement in a forward direction and in the preferred arrangement a limited degree of downward movement of the forward portion of the head at least as the head approaches its extreme forward position; 70 motion of the reverse characters being imparted to the head in the reverse order in lowering it on to the boot.

One feature of the invention is the provision of means to impart such motion to 75 the head.

As the present trend of taste in automobile vehicle body design is to require that the boot of the car is inclined inward in a forward direction from the base and go outer end, being either formed by intersecting planes or more usually by areuate or curved portions which give the boot in longitudinal section a form more or less closely corresponding with a segment of 85 an ellipse whose major axis is generally in the fore and aft direction of the body, the means for imparting motion to the head is of a character adapted to secure substantially throughout the movement imparted to 90 the head from its lowered position, motion in a forward direction in addition to motion in an upward direction.

Preferably, in accordance with the invention, adjacent to each of the sides of the 95 head such that they will be concealed from

view by the head when it is raised, there are provided struts adapted to be extended in an upward direction in imparting motion to the head in raising it and forming a support for the head as it is moved in a forward direction, the roof extending when moving forward in cantilever fashion from the struts, while adjacent to the lower and outer end of the head there are provided runners or trolleys engaging in guides or tracks provided on and conforming with the fact of the boot.

Conveniently in accordance with the invention the means for imparting motion to the head comprises a cam or cams co-operating with the struts or each of them to impart motion thereto in causing the ends thereof in engagement with the head to be raised and lowered and endless chains adapted to impart motion to the trolleys or runners located adjacent to the rear and lower extremity of the head.

The cam or each of them may be arranged to move in a rectilinear path being guided by V rollers and for imparting such motion to the cams any appropriate means may be employed, for instance the cams may be arranged to be moved manually, by an electric motor or through a reduction gear comprising for instance a screw-threaded shaft engaging a nut associated with a cam.

Preferably however, hydraulic means is employed for imparting motion to the cam or cams and also to the trolleys or runners.

The cam may be arranged in association with a cam follower connected with a short rack which through a pinion and gear wheel transmits motion to the struts which are also provided with rack teeth engaging a gear wheel so as to increase the upward or outward motion imparted to the upper ends of the struts and thus to increase their effective length in for instance a ratio of 3 : 1 with respect to the motion imparted to the cam follower.

The cam and the mechanism in question may be confined to one side of the car boot in which case the gear wheel referred to may be duplicated on the other side of the car boot and being engaged with the first-mentioned gear wheel by a cross-shaft.

On each end of this cross-shaft there may be provided simple universal couplings to take up misalignment and to allow for 'weaving' of the whole body when the car is in position.

Further, one of these couplings may incorporate or be associated with means for permitting angular or rotary adjustment between the two gear wheels to secure synchronisation of their rotation and thus to secure adjustment of the struts relatively one to the other so that their upper ends are at the same height.

For imparting motion to the trolleys or runners associated with the head there is conveniently employed an endless chain, one adjacent to each side of the boot, which may be of the roller or rocker joint type running over suitably disposed sprockets at fixed positions in the boot and over a sprocket on a shaft on which there is provided a spur wheel engaging a rack formed in one with or secured to the cam. 75

The chains are preferably further guided by arranging them to run along the bottom of the track in which the runners or trolleys are guided and with each of the chains there is provided a jockey sprocket.

As will be understood the relation between the movement secured by the cam and that secured by movement of the chains must be such that the upward motion imparted to the struts must bear a fixed relation corresponding with the motion imparted to the trolleys or runners and these may comprise rollers having curved or V peripheral faces engaging in channel members of like formation secured on or provided in the boot.

Rollers are provided on the strut elements engaging correspondingly formed channel members associated with the roof portion of the hood, the rollers being for instance frusto-conical or substantially so and the channels being formed with correspondingly shaped internal faces.

The channels extend longitudinally to the roof portion of the head, the channel on one side being connected with the channel on the other side by a cross member, the outer profile of which determines the form in cross section of the head which may be closed with an aluminium skin pulled on to a light steel frame, the bottom edge of which may be formed by a steel tube and strip secured to the cross-members and designed to engage between it and the edge of the skin which is preferably taken about a rod which may be sectionalised and extends from the forward portion of the head to the rearward portion thereof and then downward to the base of the head, a flange provided on a length of rubber tubing adapted to be deformed and thus form when the head is erected a weather-tight joint or weather seal with the adjacent edges of the windows and with the skin of the boot when lowered.

The channels provided in the head may be dimensioned so that when the head is fully erected the rollers on the struts will be disengaged from them and to facilitate their re-engagement in lowering the head the rear ends of the channels may be opened out or splayed.

When so disengaged and when as is preferred the centre of the forward end of the

head is engaged with locating and securing means provided at a corresponding position on the upper portion of the wind screen frame, the head will in effect have a three point suspension or connection with the body.

The locating and securing means may be a spigot adapted to enter a recess in the forward portion of the head, the spigot being preferably tapered.

The spigots and the recess are preferably tapered, the latter being conveniently a taper bored bush soft rubber bonded to the forward portion of the head so that it may move not only laterally but axially.

Further to ensure a weather-tight joint between the forward portion of the head and the corresponding portion of the wind-screen frame, the upper member of the windscreen frame may be formed to provide a weather joint with the foremost transverse member of the head and to provide a seating therefor adapted to prevent displacement of the head if undue pressure were applied to it.

Thus this member of the windscreen frame may be provided with a ledge or lip against which a correspondingly formed element on the foremost transverse member 30 of the head will seat and form a labyrinthine joint of such character as to promote the draining of any water entering at the junction between the head and the windscreen frame.

At this point it may be again remarked that the limited degree of downward motion of the head as it approaches its final erect position due for instance to the shape of the cam or cams promotes the securing of a weather-tight joint which may further be promoted by the provision of a rubber tube type jointing material similar to that provided on the sides of the head.

As above stated, manually, electrically or hydraulically operated mechanism may be provided for raising and lowering the head.

Thus there may be employed a self-

contained electric motor adapted through mechanical means to impart motion to the head or such a motor may be arranged with a driving pump in a hydraulic system or the pump may be arranged to be actuated by an engine or manually.

In the latter case a hydraulic hand pump 55 may be arranged between the two front seats so that it may be operated by the driver or passenger when seated in the vehicle and connected with a hydraulic ram adapted where a cam is provided for raising 60 and lowering the head struts to impart motion to the cam.

The pump, the construction of which is described in my co-pending Application No. 19015/47, may as its main structural 65 feature comprise means ensuring that for a substantially constant effort on the operating handle it generates any pressure demanded of it by an opposing resistance, and to this end means may be provided for 70 automatically adjusting or compensating the mechanical advantage of the handle over the pumping cylinders; in other words the displacement of the pump may be arranged to vary inversely with the pressure 75 or load against which it is operating.

Thus the fulcrum of the lever may be arranged to be displaced by increase in pressure in order to reduce the ratio between the lengths of two arms of the lever. 80

Preferably the pump is arranged to be double acting and it may be associated with an oil reservoir suitably positioned in the body of the car and for instance adjacent to the dashboard and designed to make up 85 any loss of oil in the hydraulic system which is a fixed or continuous one in the sense that oil leaving the pump is normally replaced by oil returning to it.

In the connection between the pump and 90 the ram there is provided a selector valve and the ram is preferably arranged to retract when the head is being raised and extend when the head is being lowered.

Dated this 15th day of July, 1947.

MARKS & CLERK.

#### COMPLETE SPECIFICATION

##### Improvements in and relating to Bodies for Automobile Vehicles.

I, ANTHONY HARVEY CROUCHER, a British Subject, of 5, Medina Avenue, Hinchley Wood, Esher, in the County of Surrey, do hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:

This invention relates to vehicle bodies of the kind having a boot located behind 105 that portion which provides seating accommodation and rigid head including a roof and rear panel, each of dished formation,

or in other words provided with side flanges mounted on the body so as to be capable of being moved into a forward position to 110 form with a front screen and side screens a closed body and into a rearward and downward position in which the side flanges of the head will seat upon or engage against portions of the boot which in profile correspond with the profile of the side flanges, that is to say the line forming the lower edges of the side flanges and having engaging tracks on or in the boot runners or trolleys connected with endless chains run- 115 120

ning over suitably disposed sprockets to which motion is imparted in the raising or lowering operation.

The object of the invention is to provide 5 an improved construction of body of this kind.

According to the invention adjacent to each of the sides of the head such that they will be concealed from view by the head 10 when it is raised, there are provided struts adapted to be extended in an upward direction in imparting motion to the head in raising it and forming a support for the head as it is moved in a forward direction, 15 the roof extending when moving forward in cantilever fashion from the struts and that the means for imparting motion to the head comprises a cam or cams co-operating with the struts or each of them to impart 20 motion thereto in causing the ends thereof in engagement with the head to be raised and lowered.

Conveniently in accordance with the invention the means for imparting motion to 25 the head comprises a cam or cams co-operating with the struts or each of them to impart motion thereto in causing the ends thereof in engagement with the head to be raised and lowered and endless chains 30 adapted to impart motion to the trolleys or runners located adjacent to the rear and lower extremity of the head.

The cam or each of them may be arranged to move in a rectilinear path being 35 for instance guided by V rollers and for imparting such motion to the cams any appropriate means may be employed, for instance the cams may be arranged to be moved manually, by an electric motor or 40 through a reduction gear comprising for instance a screw-threaded shaft engaging a nut associated with a cam.

Preferably however, hydraulic means is employed for imparting motion to the cam 45 or cams and also to the trolleys or runners.

The cam may be arranged in association with a cam follower connected with a short rack which through a pinion and gear wheel transmits motion to the struts which 50 are also provided with rack teeth engaging a gear wheel so as to increase the upward or outward motion imparted to the upper ends of the struts and thus to increase their effective length in for instance a ratio of 55 3:1 with respect to the motion imparted to the cam follower.

The cam and the mechanism in question may be confined to one side of the car boot in which case the gear wheel referred to 60 may be duplicated on the other side of the car boot and being engaged with the first-mentioned gear wheel by a cross-shaft.

On each end of this cross shaft there may be provided simple universal couplings to 65 take up misalignment and to allow for

'weaving' of the whole body when the car is in position.

Further, one of these couplings may incorporate or be associated with means for permitting angular or rotary adjustment 70 between the two gear wheels to secure synchronisation of their rotation and thus to secure adjustment of the struts relatively one to the other so that their upper ends are at the same height. 75

The endless chains which may be of the roller or rocker joint type for imparting motion to the trolleys or runners associated with the head run over suitably disposed sprockets at fixed positions in the boot and 80 over a sprocket on a shaft on which there is provided a spur wheel engaging a rack formed in one with or secured to the cam.

The chains are preferably further guided by arranging them to run along the 85 bottom of the track in which the runners or trolleys are guided and with each of the chains there is provided a jockey sprocket.

As will be understood the relation between the movement secured by the cam 90 and that secured by movement of the chains must be such that the upward motion imparted to the struts must bear a fixed relation corresponding with the motion imparted to the trolleys or runners and these 95 may comprise rollers having curved or V peripheral faces engaging in channel members of like formation secured on or provided in the boot.

Preferably rollers are provided on the 100 strut elements engaging correspondingly formed channel members associated with the roof portion of the hood, the rollers being for instance frusto-conical or substantially so and the channels being formed 105 with correspondingly shaped internal faces.

The channels extend longitudinally to the roof portion of the head, the channel on one side being connected with the channel on the other side by a cross member, 110 the outer profile of which determines the form in cross section of the head which may be closed with an aluminium skin pulled on to a light steel frame, the bottom edge of which may be formed by a steel tube 115 and strip secured to the cross-members and designed to engage between it and the edge of the skin which is preferably taken about a rod which may be sectionalised and extends from the forward portion of the head 120 to the rearward portion thereof and then downward to the base of the head, a flange provided on a length of rubber tubing adapted to be deformed and thus form when the head is erected a weather-tight 125 joint or weather seal with the adjacent edges of the windows and with the skin of the boot when lowered.

The channels provided in the head may be dimensioned so that when the head is 130

fully erected the rollers on the struts will be disengaged from them and to facilitate their re-engagement in lowering the head the rear ends of the channels may be opened out or splayed.

When so disengaged and when as is preferred the centre of the forward end of the head is engaged with locating and securing means provided at a corresponding position on the upper portion of the wind screen frame, the head will in effect have a three point suspension or connection with the body.

The locating and securing means may be 15 a spigot adapted to enter a recess in the forward portion of the head, the spigot being preferably tapered.

The spigots and the recess are preferably tapered, the latter being conveniently a 20 taper bored bush soft rubber bonded to the forward portion of the head so that it may move not only laterally but axially.

Further to ensure a weather-tight joint between the forward portion of the head 25 and the corresponding portion of the windscreen frame, the upper member of the windscreen frame may be formed to provide a weather joint with the foremost transverse member of the head and to provide 30 a seating therefore adapted to prevent displacement of the head if undue pressure were applied to it.

Thus this member of the windscreen frame may be provided with a ledge or lip 35 against which a correspondingly formed element on the foremost transverse member of the head will seat and form a labyrinthine joint of such character as to promote the draining of any water entering at the 40 junction between the head and the windscreen frame.

Preferably in accordance with the invention means is provided for imparting a limited degree of downward motion to the 45 head as it is brought into its fully forward position and a limited increase in rate of downward motion and inward or forward motion to it as it approaches the rearward position in order in the latter case to bring 50 the side flanges into the position in which they seat firmly on the boot and to ensure that at intermediate positions there is a clearance between the side flanges and the adjacent surfaces of the boot.

55 In most, if not in all cases, initially in the operation of moving the head upward and in a forward direction, that is into the "closed" position, the rate of upward movement initially must be greater than that of 60 the forward motion with a subsequent reduction of the rate of movement in an upward direction relative to the rate of movement in a forward direction and in the preferred arrangement a limited degree of 65 downward movement of the forward por-

tion of the head at least as the head approaches its extreme forward position, motion of the reverse characters being imparted to the head in the reverse order in lowering it on to the boot. 70

One feature of the invention is the provision of means to impart such motion to the head.

At this point it may be again remarked that the limited degree of downward motion 75 of the head as it approaches its final erect position due for instance to the shape of the cam or cams promotes the securing of a weather-tight joint which may further be promoted by the provision of a rubber tube 80 type jointing material similar to that provided on the sides of the head.

As above stated, manually, electrically or hydraulically operated mechanism may be provided for raising and lowering the 85 head.

Thus there may be employed a self-contained electric motor adapted through mechanical means to impart motion to the head or such a motor may be arranged with 90 a driving pump in a hydraulic system or the pump may be arranged to be actuated by an engine or manually.

In the latter case a hydraulic hand pump 95 may be arranged between the two front seats so that it may be operated by the driver or passenger when seated in the vehicle and connected with a hydraulic ram adapted where a cam is provided for raising and lowering the head struts to impart 100 motion to the cam.

The pump, the construction of which is described in my co-pending Application No. 19015/47, may as its main structural feature comprise means ensuring that for a 105 substantially constant effort on the operating handle it generates and pressure demanded of it by an opposing resistance, and to this end means may be provided for automatically adjusting or compensating 110 the mechanical advantage of the handle over the pumping cylinders; in other words the displacement of the pump may be arranged to vary inversely with the pressure or load against which it is operating. 115

Thus the fulcrum of the lever may be arranged to be displaced by increase in pressure in order to reduce the ratio between the lengths of two arms of the lever.

Preferably the pump is arranged to be 120 double acting and it may be associated with an oil reservoir suitably positioned in the body of the car and for instance adjacent to the dashboard and designed to make up any loss of oil in the hydraulic system 125 which is a fixed or continuous one in the sense that oil leaving the pump is normally replaced by oil returning to it.

In the connection between the pump and the ram there is provided a selector valve 130

and the ram is preferably arranged to retract when the head is being raised and extend when the head is being lowered.

A preferred construction in accordance with the invention is illustrated by way of example with reference to the accompanying drawings, in which :—

Fig. 1 is a fragmentary view in elevation ; Fig. 2 a corresponding plan view ;

10 Fig. 3 a similar view in end elevation of a body in accordance with the invention with the head in the raised position ;

15 Figs. 4, 5 and 6 being corresponding views with the head in the lowered position ;

Fig. 7 is a view in elevation showing certain of the mechanical details ;

Fig. 8 being a corresponding view on a plane indicated by the line A—A of Fig. 7 ;

20 Fig. 9 being a corresponding view with the head in the up position ;

Fig. 10 being a plan view in section on a plane indicated by the line B—B of Fig. 7 ;

25 Fig. 11 a plan view showing certain of the elements ;

Fig. 12 is a view in end elevation corresponding generally with Fig. 7 ;

30 Fig. 13 is a fragmentary view illustrating the engagement of the lower rear portion of the head with runners on the boot or tail :

Fig. 14 is a fragmentary view in section of the roof of the head ;

35 Fig. 15 is a fragmentary view in section on planes indicated by the line X—X of Fig. 13 ;

Fig. 16 is a view in sectional elevation of the forward part of the body showing 40 means for imparting motion to the head in raising it ;

Fig. 17 being a sectional plan view on the planes indicated by the line E—E of Fig. 15 ;

45 Fig. 18 showing the positions assumed by the head in the operation of raising and lowering it.

Referring to the drawings, on the body 1 of the vehicle there is provided a head 2 50 the lower edge 3 of which conforms with the upper face 4 of the boot 5 or tail of the body.

Adjacent to the sides of the body, in a position such that they will be concealed 55 from view by the head when it is raised, there are provided struts 6 Fig. 7 adapted to be extended in an upward direction in imparting motion to the head in raising it and forming a support for the head as it is 60 moved forward, the roof portion of which extends when moving forward in cantilever fashion from the struts.

The means for imparting motion to the head in raising and lowering includes 65 double acting hydraulic pump 7 Figs. 16

and 17 which is actuated by a hand lever 8 the pump delivering liquid, the supply of which is made up from the reservoir 9 by way of a reversing valve 10 either in the direction to raise the head or 70 to control its lowering, the pump being connected to a ram 11 adapted to exert thrust on a cam 12 situated on the near side of the boot which is guided and supported by V-groove rollers 13. With this cam operates a cam follower 14 which is also V-grooved and consequently helps to restrain the cam from sidewise motion.

The cam follower is connected by an arm 15 with a rack 16 which is engaged on 80 its forward side by two V-rollers 17 running in a groove in the back of the rack and at the front side by a pinion 18 which is shrouded, provided with side or end plates projecting beyond the tips of its teeth and 85 engaging with the sides of the rack.

The pinion is connected to a spindle 19 on which is mounted a gear wheel 20 the pinion and gear wheel transmitting and increasing by 3:1 the motion imparted to the 90 struts 6.

The spindle 19 extends across the body and is furnished with a gear wheel equivalent to 20 engaging the other of the 95 struts.

In this cross-shaft adjacent to each end there is preferably provided a simple universal coupling to take up misalignment and to allow for 'weaving' of the whole body when the car is in motion, and one of 100 these couplings preferably incorporates means for providing adjustment so as to be able to align the structure relatively to each other.

The strut at the near side is engaged by 105 a grooved roller 22 carried by the rack, the object of this arrangement being that the one supports the other in the event of excessive side load conditions occurring.

The struts on both sides are guided by 110 two further V-rollers 23, on the front sides or edges the gear wheels 20 operating also to retain them in position, the wheels being furnished with side or end plates or discs engaging the sides of the strut. 115

In addition the struts are engaged or guided by further pinions 24.

The tops of the struts are formed with rearwardly extending portions 25 to enable the front of the head to be kept outside the 120 rear seat headroom space when nearing the lowering cycle (the struts proper have to move forward in raising the head so that they come through the top of the waist of the body within the rear bottom edge of 125 the head).

The cam 12 is furnished with a rack 26 engaging a pinion 27 secured to a shaft 28 to which is also secured a chain sprocket 29 on one side of the body and a similar 130

chain sprocket on the opposite side of the body, these sprockets engaging chains 30 which are guided in part by sprockets 31 and by channels 32 provided at the sides 5 of the boot.

The chains are connected with trolleys 33 these trolleys being furnished, see Fig. 13, with convex faced rollers 34 engaging in the channels referred to and being connected by an arm 35 furnishing a pivotal attachment of the trolleys with the adjacent portion of the head, that is to say, the rear bottom portion thereof.

These channels are sunk, as will be seen, 15 below the skin 36 of the boot, the centre line 37 of these tracks being shown in Fig. 18 which shows twenty-two positions the trolleys and the head will successively take up in raising and lowering it, the ends of 20 these channels being inclined so as to effect the pulling down of the head toward the conclusion of the raising and lowering operations.

The head itself, see Figs. 14 and 15, 25 comprises an aluminium skin 38 the edge 39 of which forms a bead reinforced by a core 40 which is formed in sections, the sections being secured in position by screws.

30 This skin is stretched over a framework which comprises two longitudinally extending runners 41 connected at intervals by transverse members 42 which may be made up from thin steel dished pressings 35 riveted or spot welded together as shown in Fig. 14 and between this framework and the skin is inserted soft rubber strips 43 and in addition between the edge of the skin and the edge of the framework is inserted 40 a soft rubber packing 44 which is designed to secure a weather-tight joint 45 with the adjacent windows 46 or other adjacent parts of the body.

The runners 41 are designed to engage 45 conical rollers 47 provided on the upper ends 25 of the struts 6.

In its final downward or upward motion of the head, these runners become free from the rollers the rear ends of which are 50 splayed out to facilitate the engagement and disengagement of the rollers and the tracks, and in its final forward movement, a conical and inclined recess 48 Fig. 4 in the forward part 49 of the head engages 55 the upwardly and outwardly extending pin 50, the inclination of this pin operating to draw the head slightly downwards so as to give a weather-tight joint with the upper member 51 of the windscreen 52.

60 Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:—

65 1. A vehicle body of the kind having a

boot located behind that portion which provides seating accommodation and a rigid head including a roof and rear panel, each of dished formation, or in other words provided with side flanges mounted on the 70 body so as to be capable of being moved into a forward position to form with a front screen and side screens a closed body and into a rearward and downward position in which the side flanges of the head will seat 75 upon or engage against portions of the body forming the boot which in profile correspond with the profile of the side flanges, that is to say the line forming the lower edges of the side flanges and having engaging 80 in tracks on or in the boot runners or trolleys connected with endless chains running over suitably disposed sprockets to which motion is imparted in the raising or lowering operation characterised in this, 85 that adjacent to each of the sides of the head such that they will be concealed from view by the head when it is raised, there are provided struts adapted to be extended in an upward direction in imparting motion 90 to the head in raising it and forming a support for the head as it is moved in a forward direction, the roof extending when moving forward in cantilever fashion from the struts and that the means for imparting 95 motion to the head comprises a cam or cams co-operating with the struts or each of them to impart motion thereto in causing the ends thereof in engagement with the head to be raised and lowered. 100

2. A vehicle body as claimed in Claim 1, in which the cam or each of them is arranged to move in a rectilinear path.

3. A vehicle body as claimed in Claims 1 or 2 in which hydraulic means is provided 105 for imparting motion to the cam or cams and also to the trolleys or runners.

4. A vehicle body as claimed in Claims 1, 2 or 3, in which the cam is arranged in association with a cam follower connected 110 with a short rack which through a pinion and gear wheel transmits motion to the struts which are also provided with rack teeth engaging a gear wheel so as to increase the upward or outward motion imparted to the upper ends of the struts and thus to increase their effective length in for instance a ratio of 3:1 with respect to the motion imparted to the cam follower. 115

5. A vehicle body as claimed in any of 120 the preceding claims in which the endless chains running over suitably disposed sprockets at fixed positions in the boot are set in engagement with a further sprocket on a shaft on which there is provided a 125 spur wheel engaging a rack formed in one with or secured to the cam.

6. A vehicle body as claimed in any of 130 the preceding Claims 4 to 5 in which rollers are provided on the strut elements engag-

ing correspondingly formed channel members associated with the roof portion of the hood.

7. A vehicle body as claimed in Claim 6  
5 in which the rollers are frusto-conical or substantially so and the channels are formed with correspondingly shaped internal faces.

8. A vehicle body as claimed in any of  
10 the preceding claims, in which centre of the forward end of the head is provided with locating and securing means co-operating with correspondingly positioned means on the upper portion of the wind-  
15 screen frame.

9. A vehicle body as claimed in Claim 8,  
in which means is provided for securing initially in the operation of moving the

head upward and in to its forward position that is into the "closed" position, a rate of 20 upward movement greater than that of the forward motion with a subsequent reduction of the rate of movement in an upward direction relative to the rate of movement 25 in a forward direction.

10. A vehicle body as claimed in Claim 9, in which means is provided for securing a limited degree of downward movement of the forward portion of the head at least as the head approaches its extreme forward 30 position and for securing motion of the reverse character in lowering the head on to the boot.

Dated this 8th day of July, 1948.
